ABSTRACT

We present the results of high spatial resolution HI observations of five intrinsically compact dwarf galaxies which are currently experiencing a strong burst of star formation. The HI maps indicate that these systems have a complex and clumpy interstellar medium. Unlike typical dwarf irregular galaxies, these Blue Compact Dwarf (BCD) galaxies exhibit strong central concentrations in their neutral gas distributions which may provide a clue to the origin of their strong star-burst activity. Furthermore, while all of the systems do appear to be rotating, based on observed velocity gradients, the kinematics are complex. All systems have non-ordered kinematic structure at some level; some of the extended gas is not necessarily kinematically connected to the main system.

The observed gas distributions and kinematics place constraints on evolutionary scenarios for BCDs. Evolutionary links between BCDs, dwarf irregulars, and dwarf ellipticals have been postulated to explain their high star formation rates and low

luminosity, low metallicity nature. The BCDs appear to have higher central mass concentrations in both gas and stellar content than the dwarf irregulars, indicating that evolutionary scenarios connecting these two classes will require mass redistribution. In addition, the fact that BCDs are rotationally supported systems indicates that BCDs are unlikely to evolve into dwarf ellipticals without substantial loss of angular momentum. Thus, while such evolutionary scenarios may still be possible with the aid of mergers or tidal interactions, the isolated nature of BCDs suggests that the majority of BCDs will not fade to become objects similar to the present day dwarf ellipticals.

Subject headings: galaxies: compact — galaxies: dwarf — galaxies: individual (II Zw 40, UGC 4483, UM 439, UM 461, UM 462) — galaxies: kinematics and dynamics

1. Introduction

Dwarf galaxies provide unique probes of the star-formation process in low metallicity environments. Despite a significant amount of observational and theoretical work on these systems, we still have many unanswered questions about star formation in low mass, low metallicity objects. For instance, azimuthal averages of the HI column density indicate that the gas density in dwarf irregulars is significantly lower (by factors of 2–3) than the Toomre (1964) instability criterion throughout the star forming disk (e.g., Hunter & Plummer 1996; van Zee *et al.* 1997b; Hunter *et al.* 1998a). In contrast, preliminary work on Blue Compact Dwarf (BCD) galaxies suggests that they exceed the Toomre instability criterion in the central regions, perhaps facilitating their high star-formation rates (e.g., Taylor *et al.* 1994). While the above studies do not include the molecular gas component, primarily because it is difficult to detect in low metallicity systems (e.g., Elmegreen *et al.* 1980; Israel *et al.* 1995), the neutral gas density appears to have a regulatory role on the star-formation process in dwarf galaxies. Thus, to further investigate these regulatory processes, we have undertaken high spatial resolution observations of a small sample of BCDs, systems which are currently undergoing vigorous star-formation activity.

The class of objects known as BCDs, or H II galaxies, form a heterogeneous sample ranging from true dwarf galaxies of only $10^7 M_{\odot}$ to outlying H II regions of moderate sized galaxies. In this paper, we will use the term BCD to refer to galaxies which meet the following criteria: (1) the underlying galaxy which is hosting the strong starburst has an absolute blue magnitude fainter than -16 ; (2) the optical size is at most a few kpc; and (3) a large fraction of the optical light comes from a star burst.

The origin and duration of the starburst phase in BCDs is still unknown. One possibility is that the starburst is triggered, either by an interaction (as discussed by Taylor *et al.* 1993), or through a stochastic process. If the starburst phase in these galaxies is episodic, there should also exist in the local universe faded, or post-burst, BCDs. Several popular evolutionary scenarios

suggest that the 3 common types of dwarf galaxies (dwarf elliptical (dE), dwarf irregular (dI), and BCD) are simply 3 different evolutionary stages for low mass objects (e.g., Dekel & Silk 1986; Silk *et al.* 1987; Davies & Phillipps 1988). Studies of the stellar content and distributions in dwarf galaxies have thus far been inconclusive in regard to the feasibility of such morphological transformations (e.g., Loose & Thuan 1986; Drinkwater & Hardy 1991; James 1994; Papaderos *et al.* 1996; Sung *et al.* 1998). To date, few *kinematic* constraints have been placed on such evolutionary scenarios, in part due to the dearth of good quality, high spatial and spectral resolution observations of dwarf galaxies.

This paper presents the HI distribution and kinematics of five intrinsically compact galaxies in order to address both the regulatory role of gas density on star formation activity and the evolution of starbursting dwarf galaxies. The paper is organized as follows. The data acquisition and reduction are presented in Section 2. The HI distributions and kinematics are discussed in Sections 3 and 4, respectively. The individual galaxies are described in Section 5. A discussion of the neutral gas density distribution and star-formation threshold is presented in Section 6. In Section 7, we discuss the implications on the evolutionary history of BCDs, as derived from the neutral gas distributions and kinematics. Our conclusions are summarized in Section 8.

2. Data Acquisition and Analysis

Multiconfiguration HI observations of five BCDs were obtained with the Very Large Array⁴. Complementary optical imaging observations were obtained at several different telescopes. In this section, the procedures for observation and data reduction are discussed.

2.1. Sample Selection

To date, few high spatial resolution (5'' beams) HI synthesis observations of dwarf galaxies have been published (II Zw 40, Brinks & Klein 1988; Holmberg II, Puche *et al.* 1992; II Zw 33, Walter *et al.* 1997; I Zw 18, van Zee *et al.* 1998). We elected, therefore, to restrict the sample of galaxies to systems which had previously been observed and detected with the VLA in one of its more compact configurations (C or D). These constraints led to the selection of 3 galaxies from the Taylor *et al.* (1995) sample (UM 439, UM 461, and UM 462), II Zw 40 (Brinks & Klein 1988), and UGC 4483 (Lo *et al.* 1993) for our first attempt at high spatial resolution observations of BCD-like objects. All of the galaxies in the current sample meet the above criteria for BCDs; while UGC 4483 is not usually considered a BCD, perhaps due to its proximity, it too is vigorously forming stars at the present epoch.

⁴The Very Large Array is a facility of the National Radio Astronomy Observatory.

The physical properties of the selected galaxies are summarized in Table 1. The morphological classification and multiplicity for all systems other than UGC 4483 were taken from Telles *et al.* (1997). The classification scheme is based on the lower surface brightness isophotes, where Type I indicates irregularly shaped isophotes and Type II indicates symmetric isophotes. Of the galaxies in the current sample, only II Zw 40 is classified as a Type I BCD. The multiplicity indicates of the number of knots of star formation; all of the galaxies in this sample have at least 2 prominent HII regions. Also listed in Table 1 are the assumed distance to each system (based on H_0 of $75 \text{ km s}^{-1} \text{ Mpc}^{-1}$, except for UGC 4483 where the distance is assumed to be the same as NGC 2366 (Tolstoy *et al.* 1995)), their absolute blue magnitudes (Stavely-Smith *et al.* 1992; Telles *et al.* 1997), and oxygen abundances (Melnick *et al.* 1988; Skillman *et al.* 1994). The absolute blue magnitudes have been corrected for Galactic extinction, but not for internal extinction or for nebular contributions to the broadband luminosity. UGC 4483 is the nearest system in the sample, and also has the lowest luminosity and metallicity. The other four galaxies are at comparable distances (10–15 Mpc) and have moderate luminosities (M_B 's of -14 to -16) and metallicities (1/15 to 1/6 of solar). Also tabulated are the optical diameters at the 25th mag arcsec^{-2} isophote, in both arcsec and kpc (de Vaucouleurs *et al.* 1991; Salzer *et al.* 1998a); these systems are intrinsically small, with typical optical sizes of 1–2 kpc.

2.2. HI Imaging Observations

Observations of II Zw 40, UGC 4483, UM 439, and UM 461/2 were obtained with the VLA in its B, C, and CS configurations during 1997. The CS configuration is a modified version of the C configuration where 2 telescopes from the middle of the east/west arms are re-positioned at inner D configuration stations to provide short spacings. A summary of the observing sessions and the total on-source integration times are listed in Table 2. During all observing sessions, the correlator was used in 2AD mode with the right and left circular polarizations tuned to the same frequency; the total bandwidth was 1.56 MHz. The on-line Hanning smoothing option was selected, producing final spectral data cubes of 127 channels, each 2.6 km s^{-1} wide. Standard tasks in AIPS (Napier *et al.* 1983) were employed for calibration and preliminary data reduction. Each set of observations was calibrated separately, using 3C 48, 3C 147, and 3C 286 as flux and bandpass calibrators, and nearby continuum sources as phase calibrators. The continuum emission was removed with the AIPS task UVLIN prior to combination of uv data sets. Only II Zw 40 had substantial continuum emission associated with the system; we refer the reader to other studies for discussion of the magnitude and extent of this continuum source (e.g., Deeg *et al.* 1993; Deeg *et al.* 1997) since the current observations were not optimized for continuum detection.

The line data were transformed to the image plane with several weighting schemes and combinations of configurations. To check the data quality, maps were made for each observing session. The data cubes presented in this paper were made from the combined data sets of the B, C, and CS configuration observations. A robust weighting technique was employed by the

AIPS task IMAGR to optimize the beam shape and noise levels (Briggs 1995). The “robustness parameter” in IMAGR controls the weighting of the uv data, permitting a fine-tuning between sensitivity and resolution in the final data cubes. As currently implemented, a robustness of 5 corresponds to natural weighting of the uv data (maximizing sensitivity at the cost of spatial resolution) while a robustness of -5 corresponds to uniform weighting (maximal spatial resolution with lower sensitivity). Additionally, some maps were made with uv tapers to increase their sensitivity to low column density material. The relevant IMAGR parameters for a selected sample of the maps are listed in Table 3. Throughout this paper we will refer to the lowest resolution, tapered data cubes as the “tapered cubes”, to the robustness of 5 cubes as the “natural weight cubes”, and to the robustness of 0.5 cubes as the “intermediate weight cubes.” Selected channels from the HI data cubes are presented in Figures 1–5. All subsequent analysis was performed within the GIPSY package (van der Hulst *et al.* 1992).

To determine if the total flux density was recovered in the HI synthesis observations, total integrated profiles were constructed from the natural weight data cubes after correcting for the primary beam shape with the GIPSY task PBCORR. For all systems, the total flux density recovered in the VLA maps is in good agreement (within 5%) with previous single dish flux measurements (e.g., Staveland-Smith *et al.* 1992; van Zee *et al.* 1995; van Zee *et al.* 1997c; Salzer *et al.* 1998b; J. Salzer 1998, private communication). The total HI masses listed in Table 1 were calculated from the observed VLA flux density and the assumed distance to the system.

Moment maps of each data cube were computed in the following manner. For each galaxy, the natural weight cube was smoothed to a resolution of twice the beam; the smoothed cubes were clipped at the 2 sigma level (the noise level was measured in several line-free regions of the smoothed cube); the resultant clipped cube was then interactively blanked to remove spurious noise spikes. Signal was identified based on spatial continuity between channels. A conditional transfer was used to blank the corresponding locations in both the natural and intermediate weight data cubes (corrected for primary beam attenuation) based on the blanked, smoothed cube. Moment maps of the smoothed, natural, and intermediate weight data cubes were created with the GIPSY task MOMENTS and are presented in Figures 6–10.

2.3. Optical Imaging

Optical broad band and $H\alpha$ images were obtained during several observing runs. The observing parameters are summarized in Table 4. The observation and reduction procedures for the $H\alpha$ image of UGC 4483 are described in Skillman *et al.* (1994). $H\alpha$ and B-band images of UM 439, UM 461, UM 462, and II Zw 40 were obtained with the KPNO No. 1 0.9m telescope and followed similar reduction procedures as those described in Salzer *et al.* (1991). Finally, R-band images of II Zw 40 and UGC 4483 were obtained with the KPNO 0.9m telescope; the observation and reduction procedures for these images were identical to those described in van Zee *et al.* (1997a). Plate solutions for the optical images were derived from coordinates of at least five stars

listed in the APM catalog (Maddox *et al.* 1990) and are accurate to $0.5''$.

$H\alpha$ luminosities were computed from the observed $H\alpha$ flux and the assumed distance to each system. The $H\alpha$ luminosity was then converted to the current star-formation rate (SFR), assuming a Salpeter IMF (Hunter & Gallagher 1986):

$$\text{SFR} = 7.07 \times 10^{-42} L(H\alpha) M_{\odot} \text{ yr}^{-1}. \quad (1)$$

The current SFR and the gas depletion time scale (M_{HI}/SFR) are tabulated in Table 1. Note that if the IMF is biased towards high mass stars, the calculated gas depletion time scale will be an underestimate. The derived gas depletion time scales should be indicative, however, since observations of the stellar populations in starbursting (e.g., R136, Massey & Hunter 1998) and low metallicity environments (e.g., SMC and LMC, Massey *et al.* 1995), are consistent with a Salpeter IMF. In general, the current SFRs of the BCDs are quite high, with typical gas depletion times of approximately 1 Gyr.

3. HI Morphology

A significant fraction of the gas associated with dwarf galaxies frequently extends well beyond the optical system (e.g., DDO 154, Carignan & Beaulieu 1989; NGC 4449, Bajaja *et al.* 1994; Hunter *et al.* 1998b). The HI diameters of the BCDs (defined as the maximum diameter measured at a column density of $10^{20} \text{ atoms cm}^{-2}$) were obtained from the HI column density maps made from the low resolution tapered data cubes [Figures 6(a)–10(a)]. The HI-to-optical diameter ratios are listed in Table 1. The HI distributions of all five systems are extended, with sizes typically 3–4 times that of the optical diameter. II Zw 40 is the most extreme, with tidal tails extending approximately $8.5'$ in diameter (see Section 5.1); the HI diameter listed in Table 1 for this galaxy was obtained by measuring only the inner HI distribution, along a position angle of 115° . These results are consistent with other spatially resolved observations of BCD-type galaxies, which have also found large HI-to-optical diameter ratios (e.g., Taylor *et al.* 1994; van Zee *et al.* 1998).

The wealth of detail visible in the high spatial resolution maps is striking. Figures 6(b)–10(b) illustrate the clumpiness of the ISM on $10''$ spatial scales; even more detail is seen at the highest spatial resolution of these observations [Figures 6(c)–10(c)]. For instance, the HI distribution for UGC 4483 (linear scales of 100 to 300 pc) is clearly clumpy on all spatial scales sampled.

Inspection of the outer HI distributions reveal varying degrees of irregularity in both the column density distribution and kinematic continuity. For example, in UM 439 there appears to be an associated HI cloud to the east of the main galaxy. This cloud is likely to be a real feature since it was detected in both the C and CS configuration observations, as well as in previous D configuration observations (Taylor *et al.* 1995). Another example of this phenomenon is the gas to the north of UM 461 which appears to be kinematically distinct in the channel maps (Figure 4) but is not clearly spatially separated from the main galaxy. Similar HI clouds have been detected

around other star forming galaxies (e.g., Taylor *et al.* 1995; Wilcots *et al.* 1996). However, not all low mass galaxies have such features (e.g., van Zee *et al.* 1997b). The source and ultimate fate of the gas in the periphery of these galaxies is unclear. Several possible origins are: (1) warping of the outer gas disk; (2) ejecta from previous episodes of star formation; (3) material still in the process of accretion; or (4) tidal debris. The present observations of the gas kinematics and distribution cannot constrain the origin of this outlying material.

Azimuthal averages of the HI surface density of the BCDs are shown in Figure 11. In addition, comparison samples of dIs (van Zee *et al.* 1997b) and a few additional BCDs (Taylor *et al.* 1994) have been taken from the literature. As previously remarked by Taylor *et al.* (1994; 1995), BCDs tend to have centrally peaked surface densities. In contrast, dIs tend to have flat HI distributions in the inner regions, more similar to the HI distributions of spiral galaxies (e.g., Cayatte *et al.* 1994). Not only are the BCDs centrally concentrated, their central surface densities are significantly higher than those of the dIs. Analysis of their underlying stellar light distributions (i.e., with the starburst removed) also indicates that BCD host galaxies have more centrally concentrated stellar mass densities than dIs (e.g., Norton & Salzer 1998). Thus, the BCDs appear to have inherently different stellar and gas mass distributions than dIs. This may be a clue to the origin of strong star-formation activity in BCDs.

4. Kinematics

In this section we present the results of kinematic studies based on the HI velocity information. The observed velocity gradients are used to estimate dynamical masses in Section 4.1. In Section 4.2, we demonstrate that these systems are dominated by rotation.

4.1. Velocity Gradients

The velocity fields (Moment 1) were calculated from the blanked natural weight data cubes and are presented in Figures 6(d)–10(d). The velocity fields are complex. II Zw 40 has extensive tidal tails, with velocity continuity from the main body to the ends of the tails. In this system, the southeastern tail has a reversal in the velocity field, suggesting that the most extended material is starting to fall back onto the main galaxy (cf. Hibbard & Mihos 1995) (see Section 5.1 for further discussion of this system). While none of the other galaxies have apparent tidal features, other kinematic irregularities such as warps (e.g., UGC 4483) and kinematically distinct clumps of HI gas (e.g., UM 439) are present in all the systems. Nonetheless, despite their complexity, all have velocity gradients across the galaxy. Inspection of the channel maps (Figures 1–5) indicates a clear axis of rotation for each of the galaxies.

The complexity present in the velocity fields inhibits dynamical investigations using standard tilted-ring models. Nonetheless, we have obtained rough estimates of the dynamical masses for 3

of the 5 systems based on the observed velocity gradients and estimates of the inclination angle. In standard tilted-ring analyses, the center coordinates, systemic velocity, position angle, inclination angle, and rotation velocity are fit independently for each ring. In our analysis, we required that all parameters, except the rotation velocity, be constant for all rings. Further, the inclination angles were fixed based on the observed HI isophotal axial ratios rather than on kinematic constraints. The inclination estimates assumed a thin gas disk; if the gas disk is thick, as may be the case for low mass galaxies (e.g., Puche *et al.* 1992), the inclination will be larger than estimated here. The derived parameters are tabulated in Table 5. Tilted-ring models were not attempted for II Zw 40 or UM 461; their tabulated parameters are rough estimates at best.

Position-velocity diagrams with the derived rotation curves superposed are shown in Figure 12. The natural weight data cubes were sliced along the nominal position angles, centered at the kinematic center. As frequently found in low mass systems, the position-velocity diagrams are consistent with solid body rotation throughout the galaxy. The outermost points of the rotation curves ($R_{\max}$ and $V(R_{\max})$) are tabulated in Table 5. Dynamical masses, based on the outermost points of the rotation curves, are also tabulated in Table 5; we emphasize that these masses were derived from only rough dynamical estimates. The ratio of $M_{\text{HI}}/M_{\text{dyn}}$, typically found to be approximately 0.1 for dwarf galaxies (e.g., Skillman *et al.* 1987; van Zee *et al.* 1997b), is approximately 0.3 for these BCDs (Table 5). Whether these high values of $M_{\text{HI}}/M_{\text{dyn}}$ are significant is unclear; the kinematic models were relatively unconstrained, so it is possible that the dynamical mass has been underestimated in these calculations. Interestingly, Salzer *et al.* (1998b) also find higher than typical $M_{\text{HI}}/M_{\text{dyn}}$ for BCDs, based on single dish HI spectra. On the other hand, other spatially resolved observations of BCDs (e.g., Taylor *et al.* 1994) have resulted in values of $M_{\text{HI}}/M_{\text{dyn}}$ more typical of dwarf irregular galaxies. Further high spatial and spectral resolution observations of BCDs will be needed to determine if a large fraction of their total mass is usually in the form of neutral hydrogen.

4.2. Thermal Motions

Gaussian fits to spectral profiles from the natural weight data cubes were used to determine the average velocity dispersion for each galaxy. The median σ is tabulated in Table 5. The observed velocity dispersions are slightly higher than typically found in dwarf galaxies (e.g., Young & Lo 1996; van Zee *et al.* 1997b), but this may be due to the moderate velocity gradients and compact nature of these galaxies resulting in an additional broadening component due to rotation within the beam. Unfortunately, due to their lower signal-to-noise, velocity dispersions could not be measured accurately from the higher spatial resolution maps. Nonetheless, the observed velocity dispersions are significantly less than the rotational component in these galaxies. Thus, these systems are *rotation dominated*.

5. Individual Galaxy Characteristics

In this section we present qualitative descriptions of the individual galaxies. The new observations are also compared with previous data from the literature.

5.1. II Zw 40

II Zw 40 (UGCA 116) is one of the prototypical BCDs (e.g., Sargent & Searle 1970; Searle & Sargent 1972). It is the only galaxy in the present sample classified as a Type I BCD (Telles *et al.* 1997), and is also the only galaxy in this sample that is clearly the result of a merger. The possibility that the burst of star formation in II Zw 40 was the result of an interaction was first raised by Baldwin *et al.* (1982), based on the optical morphology. HI imaging observations confirmed the merger scenario for this galaxy and led to speculation that tidal interactions might be necessary to trigger the high star-formation rates in BCDs (Brinks & Klein 1988).

The combination of several pieces of evidence suggests that II Zw 40 is likely to be a merger, not merely the result of tidal interactions: (1) the optical morphology is consistent with that of two overlapping/merging dwarf galaxies, (2) there is no evidence for a second optical galaxy anywhere along the HI tidal tails, and (3) a strong color gradient indicates that the low surface brightness optical extensions are from an older stellar population. In particular, the LSB extension to the south of the intense star burst is quite red, indicating that these stars are from a much older population than the current starburst. The colors (corrected for Galactic reddening and nebular emission) range from $B-H \sim 1.0$ at the starburst to $B-H \sim 3.1$ in the LSB southern arm (Salzer *et al.* 1998a). The extension to the SE is intermediate in color, and also exhibits a modest level of $H\alpha$ emission, indicating that star formation may be occurring there as well. The morphology of the system, as well as the extreme color gradients, are consistent with the picture that II Zw 40 is an ongoing merger of two gas-rich dwarf galaxies.

The new high sensitivity HI maps presented here indicate that the tidal tails are even more extensive than illustrated in Brinks & Klein (1988). In many regards, the HI distribution and velocity field in II Zw 40 is reminiscent of NGC 7252, a member of Arp’s (1966) atlas which has been designated as a prototypical merging pair of galaxies by Toomre (1977). The HI tidal tails are drawn out from the optical galaxies, and a reversal in the velocity gradient is detected in the southeastern tail. While the masses of the components of the NGC 7252 merger are an order of magnitude higher than those of II Zw 40 (cf. Hibbard *et al.* 1994), it is interesting to compare these two systems. Hibbard & Mihos (1995) conducted N-body simulations of NGC 7252 and determined that the velocity reversals seen in the tidal tails of that system were due to material falling back towards the dynamical center. In both NGC 7252 and II Zw 40, the radial velocities at the ends of the tidal tails are similar to the radial velocities of the main bodies. The simulations of Hibbard & Mihos (1995) give a detailed timetable for the return of tidal material to the system. The return is spread out over several Gyr, but more than half of the gas has

returned in the first Gyr. Without a similar detailed model of II Zw 40, quantitative estimates of the fallback of material to the system is not possible (and we would encourage others to carry-out such modelling). With such modelling, it will be possible to determine if infall could sustain star formation at an elevated rate and increase the lifetime of the burst or result in a second episode of increased star formation. Since $\sim 40\%$ of the gas is in the tidal tails, the return of this gas to the main body could have a significant effect on the future star formation of the system. A modelling investigation of the low mass merger II Zw 40 could provide valuable insight into the future evolution of this system.

5.2. UGC 4483

UGC 4483, normally considered an Im galaxy, was included in the BCD sample because of its compact nature and moderate star-formation rate. If this system were placed at a distance of 10 Mpc (the typical distance of the other galaxies in this sample), it might be classified as a BCD. As mentioned previously, the BCD class is quite heterogeneous; UGC 4483 would qualify as a weak BCD in that its star forming regions contribute a large fraction of its total luminosity. On the other hand, its gas depletion time scale is fairly long, almost 10 Gyr, similar to that found for more quiescent dwarf irregulars (e.g., van Zee *et al.* 1997a).

In this system, several knots of star formation are superimposed on a low surface brightness stellar component. The brightest knot of active star formation is located to the north of the optical center and is associated with the peak neutral gas column density. As previously noted by Lo *et al.* (1993), the HI distribution extends well beyond the optical system.

This galaxy is the nearest object in the sample and thus the HI observations have the highest linear resolution, on the order of 100 pc beam^{-1} . On these small spatial scales, the HI distribution is distinctly clumpy and irregular [Figure 7(b)]. Interestingly, despite the high linear resolution of these observations, there are no obvious HI holes, such as those seen in IC 10 (Shostak & Skillman 1989), Holmberg II (Puche *et al.* 1992), and VV 794 (Taylor *et al.* 1994). Nonetheless, at this resolution a strong correlation is seen between column density peaks and sites of active star formation. Furthermore, this system allows an estimate of the effect of beam smearing on the observed peak column densities. As expected, low resolution observations have correspondingly lower peak column densities (Table 6). For instance, an increase in the spatial resolution by a factor of 5 corresponds to an increase in the observed column density by a factor of 2.

5.3. UM 439

The most intense region of star formation is located south of the center of the optical portion of UM 439 (UGC 6578), and the highest column density of HI gas occurs at this location as

well. There is weaker, more diffuse, $H\alpha$ emission over most of the central part of the galaxy, suggesting that there has been vigorous star formation occurring there in the recent past. This activity is apparently dying out. The location of the strong knot on the outskirts of the optical galaxy implies an outward propagation of star formation. Despite the appearance of recent strong activity in the central portion of the galaxy, there is no evidence for an HI hole in the middle of this object as is seen in other dwarf galaxies (Puche & Westpfahl 1994). At the distance of UM 439, however, the detection of such holes would be difficult. The neutral gas is centrally peaked, and extends well beyond the star forming regions. Previous HI mapping of this galaxy indicated the presence of extended gas to the east (van Zee *et al.* 1995; Taylor *et al.* 1995). The new observations confirm the extended structure to the east, but the total mass of this object is only $\sim 6 \times 10^6 M_{\odot}$, approximately 2% of the total HI in this system. Given its low mass and low column density, it is unlikely to be a companion to UM 439. The present observations are not able to determine the origin of this gas cloud, but it would be of great interest to determine if this extended material has been significantly enriched by previous star formation episodes.

5.4. UM 461 and UM 462

Two bright knots of active star formation dominate UM 461. The HI distribution extends well beyond the optical system. Like UM 439, the extended gas on the east side of UM 461 is kinematically complex. The extended structure visible to the SE in the Taylor *et al.* (1995) maps is not recovered here; this feature was probably introduced by solar interference in their D configuration maps (Taylor *et al.* 1996). The velocity field [Figure 9(d)] indicates that there is a velocity gradient across this system, but the field is too complex to permit rotation curve fits.

UM 462 (UGC 6850; Mk 1307) is dominated by two knots of star formation, the brighter of which is centrally located in the galaxy. The HI distribution extends well beyond the optical system and peaks near the central star forming regions. The velocity field is indicative of solid body rotation.

In contrast to the image presented in Taylor *et al.* (1995), UM 461 and UM 462 do not appear to be tidally interacting (Figure 13). Assuming that the systems are both at a distance of 13.9 Mpc, the linear separation between the two systems is approximately 70 kpc (40 times the average of their optical diameters, and 11 times their mean HI diameters). Assuming a relative velocity of $\sim 100 \text{ km s}^{-1}$, the crossing time is 7×10^8 years, significantly longer than the age of the star bursts (expected to be less than 100 Myr). Furthermore, both UM 461 and UM 462 are classified as Type II BCDs by Telles *et al.* (1997), indicating that they are symmetric objects in the optical. Thus, even if these systems are physically associated, it is unlikely that they induced the high rates of star formation in each other.

6. Gas Density Thresholds

As discussed in Section 3, BCDs tend to have higher central gas mass concentrations than dIs, suggesting an intrinsic difference in the HI distribution between quiescent dIs and BCDs. Previous studies of the neutral gas distribution in BCDs and dIs indicate that the gas column density can play a critical role in regulating star-formation activity (e.g., Skillman *et al.* 1987; Taylor *et al.* 1994; Hunter & Plummer 1996; van Zee *et al.* 1997b; Hunter *et al.* 1998a). In studies such as these, the gas density should include both the atomic and molecular gas components. In practice, however, the molecular gas distribution is usually unknown due to the difficulty detecting CO in low mass, low metallicity galaxies (e.g., Elmegreen *et al.* 1980). Furthermore, even when CO is detected, the conversion factor from CO to H₂ column density is highly uncertain (e.g., Verter & Hodge 1995; Wilson 1995). Thus, we note that the column densities quoted in the following discussion are lower limits since we have elected to apply no correction for the contribution of molecular gas. We do, however, include a correction for helium: $N_{\text{gas}} = 4/3 N_{\text{HI}}$. The observed peak neutral hydrogen gas column densities (N_{HI}) and the corresponding neutral gas surface density (corrected for inclination and helium content, Σ_g) are tabulated in Table 6.

Many of the gas density studies rely on azimuthal averages of the gas surface density and star-formation rate, such as those illustrated in Figure 11. In disk systems, the Toomre (1964) instability criterion provides a natural threshold density with which to compare azimuthally averaged radial density profiles. The Toomre criterion represents the balance between gravitational collapse and rotational shear and thermal pressure; we note that in the limit of zero rotational shear (solid body rotation), this criterion is still valid. We have tabulated the value of the Toomre instability criterion ($< \Sigma_c >$) for UGC 4483, UM 439, and UM 462 in Table 6, assuming the kinematic parameters from Section 4 and solid body rotation throughout the disk (II Zw 40 and UM 461 have been excluded from this analysis since their kinematic parameters were unconstrained). In contrast to the results for dIs, where the global gas density rarely, if ever, exceeds the Toomre instability criterion (e.g., van Zee *et al.* 1997b; Hunter *et al.* 1998a), the Toomre value is exceeded in the central regions of all three BCDs, suggesting that star-formation activity should be enhanced in the inner regions of these galaxies.

While radial profiles are potentially useful as global indicators of star-formation activity, azimuthal averages tend to dampen star formation signatures in systems where star formation is a local process, such as irregular and dwarf galaxies (e.g., van Zee *et al.* 1997b). Visual inspection of Figures 6(c)–10(c) indicates a good correlation between sites of active star formation and local peaks in the HI column density. Intensity profiles for both the HI and H α emission are presented in Figure 14; each profile is centered on the peak H α emission feature and is oriented such that additional HII regions are included in the profile. In addition to the five BCDs in this sample, a panel for I Zw 18 is also included (van Zee *et al.* 1998). Upon detailed inspection of these intensity profiles, it is clear that the high rate of star-formation activity in the BCDs has had an impact on the neutral gas surface density. In particular, while situated near the column density peak, the brightest HII regions in II Zw 40 and UGC 4483 are actually located in slight depressions.

This is likely due to either strong stellar winds evacuating the gas or photoionization from the UV continuum of the OB stars. Despite this evidence of local feedback from the star-formation activity on the neutral medium, the overall impression is that sites of active star formation are associated with regions of high column density ($2\text{--}4 \times 10^{21}$ atoms cm^{-2}).

It has been hypothesized that the empirical critical star-formation threshold density (10^{21} atoms cm^{-2}) found in many types of galaxies could correspond to a critical column density of dust necessary to shield molecular gas from UV radiation (Federman *et al.* 1979). If so, this suggests that the empirical threshold might be a function of metallicity. The BCD sample which, with the addition of I Zw 18 (van Zee *et al.* 1998), spans a factor of 10 in metallicity, provides an opportunity to test this hypothesis. In Figure 15(a) the observed peak column densities are plotted as a function of metallicity for the BCD sample and for dI galaxies from the literature (Skillman *et al.* 1988; Shostak & Skillman 1989; Lo *et al.* 1993; van Zee *et al.* 1997b). The oxygen abundances for the dI galaxies and I Zw 18 were also taken from the literature (Skillman *et al.* 1989; Skillman & Kennicutt 1993; van Zee *et al.* 1996; van Zee *et al.* 1997a). While the peak column density may not be the most appropriate indicator (a “threshold” density might be more useful, but is rarely reported in the literature), it is a useful diagnostic, particularly in BCDs where one can assume that the HII regions have not significantly aged. The peak column densities have not been corrected for inclination or beam effects, so a large scatter in this plot is not unexpected. The total number of objects is still small, but there is no obvious trend for an increase in column density with decreasing metallicity; rather, the most obvious trend in this plot is that dIs clearly have lower column densities than the BCDs at similar metallicities. By removing the restriction of previous knowledge of the oxygen abundance, larger sample sizes for both the BCDs and dIs are possible. In Figure 15(b), the distributions of peak column densities for BCDs and dIs are shown. The BCD sample includes data from the present sample, Taylor *et al.* (1994), and van Zee *et al.* (1998); the dI sample includes those galaxies in the above literature compilation as well as Skillman *et al.* (1987), Côté (1995), Kobulnicky & Skillman (1995), and Hunter *et al.* (1996). Again, the observed column densities have not been corrected for inclination or for beam-smearing effects, but the BCDs, on average, have higher peak column densities than the dIs. This trend may explain, or be a result of, the high rates of star formation in BCDs.

7. Evolutionary Scenarios

As recognized by Searle & Sargent (1972), the defining characteristic of a BCD – a bright, compact, star burst – must be a short lived phenomenon (see Table 1 for examples of gas depletion timescales). In fact, the current star-formation rate must be higher than the average past rate in these systems in order to explain their compact, low luminosity, low metallicity nature. It was thus hypothesized that these galaxies undergo episodic bursts of star formation, with the corresponding conclusion that they spend a fraction of their lifetime in a quiescent state. BCDs in a quiescent state have not yet been found, however, in part due to the difficulty of identifying such

objects. For instance, it is still unclear what these galaxies should look like since their high rate of star formation will presumably affect many physical properties such as the ISM, total luminosity, colors, etc. Nonetheless, it is natural to wonder if there may be an evolutionary link between the three main classes of low mass galaxies: dI, dE, and BCDs (e.g., Skillman 1996). Below we discuss possible evolutionary scenarios for both pre- and post-BCDs.

In general, BCDs and dIs have many similar global properties, with the exception of optical surface brightness and optical size (e.g., Hoffman *et al.* 1989). For instance, both dIs and BCDs can have large, extended HI distributions. However, in contrast to the extensive HI envelopes around many quiescent dIs (e.g., van Zee *et al.* 1997b), the HI envelopes around BCDs have many kinematic irregularities. The BCDs may still be in the process of collapse, or this may be the result of their high rates of star formation. Another major difference between BCDs and dIs is that the BCDs have higher central mass concentrations in both gas and stellar content. This latter point has been the major stumbling block for simple evolution models between BCDs and dIs since it indicates that mass redistribution will be necessary before a BCD can fade into a dI. An alternative view might be that BCDs do not evolve into low surface brightness dIs at all (because of the differences in their kinematics and gas content), but rather that their high central mass concentrations simply are normal for these galaxies. In this scenario, one would think of dIs as possessing a range in their central surface brightness/central mass densities, from very low (e.g., LSB dwarfs) to very high. The galaxies we see as BCDs would simply represent the extreme end of this continuum of central mass densities. The star burst activity would then be a natural consequence of the physical properties of the galaxies: objects with high central mass concentrations would preferentially be able to host and sustain a major starburst.

It has also been hypothesized that BCDs could evolve into dEs, either if the burst uses the available gas, or if the ISM is disrupted as the burst evolves (e.g., Dekel & Silk 1986; Davies & Phillipps 1988; Marlowe *et al.* 1995; Telles *et al.* 1997). The blow-away scenario, however, is more difficult than previously thought (Mac Low & Ferrara 1998). Furthermore, while some BCDs are morphologically similar to the dEs, their kinematics are quite different. As Ferguson & Binggeli (1994) emphatically state, “dwarf ellipticals are not supported by rotation.” Admittedly, only a few dEs have been observed, but almost all have stellar rotation velocities less than 2 km s^{-1} (e.g., NGC 185 and NGC 205, Bender *et al.* 1991; VCC 351, Bender & Nieto 1990). The few exceptions (NGC 147, Bender *et al.* 1991; IC 794, Bender & Nieto 1990) have rotation velocities of only $10\text{--}15 \text{ km s}^{-1}$ which is significantly less than the rotation velocities for the BCDs in this sample. Interestingly, the HI gas associated with NGC 205 does have a significant velocity gradient, but this gas may have been captured recently (Young & Lo 1997). Nonetheless, it appears that most dEs are not supported by rotation while many (all?) BCDs are rotation dominated. Thus, loss of angular momentum would be necessary before a BCD could evolve into a dE. Furthermore, one additional argument against BCD to dE evolution comes from environmental considerations: most dEs are found in clusters or as companions to massive galaxies while BCDs are typically field objects. In fact, dEs are among the most strongly clustered galaxies known (Ferguson & Sandage

1989), while BCDs are among the least clustered (Iovino *et al.* 1988; Salzer & Rosenberg 1994; Pustil’nik *et al.* 1995). If the previous generation of BCDs all evolved into dE galaxies, it would lead to a large population of unclustered dEs, which is not observed to exist. Note that we cannot rule out the possibility that the present day dEs evolve through a BCD-like phase during their early evolution. Rather, we suggest that the BCDs we see today will not evolve into dEs.

One solution to allow a BCD to dE evolutionary scenario is to hypothesize that interactions with other galaxies can enable the BCD to lose the necessary angular momentum. Interactions have also been invoked to explain the high rate of star formation in BCDs (e.g., Taylor *et al.* 1993; Taylor *et al.* 1995; Walter *et al.* 1997), and thus are an extremely appealing mechanism to not only explain the initiation of star-formation activity, but also the subsequent evolution of a BCD. However, based on a search for optical companions, Telles & Terlevich (1995) found that a significant fraction of BCDs were isolated. Furthermore, of the five BCDs in this sample, only one (II Zw 40) is clearly the result of an interaction. Thus, while an interaction is certainly one mechanism by which star formation can be enhanced in BCDs, it is not the only one, and possibly not even the most common.

Further observational evidence will be needed to determine the ultimate fate of BCDs. For instance, optical surface photometry for large, unbiased, samples of dIs would be useful to determine if BCDs simply form the extreme end of a continuum of dI properties. The study of Patterson & Thuan (1996) represents a good start in this direction, but more data are needed. In addition, studies of the gas content in BCDs, dIs, and dEs would be beneficial for identification of systematic trends in gas content, and to confirm that most dEs are gas-poor. Further, detailed studies of the mass distributions (stellar, gas, and total) in all types of dwarf galaxies will be necessary to determine if BCDs, dIs, and dEs form a common family. Finally, kinematic studies, particularly of the stellar distributions in dEs, will be crucial for understanding the relationships between these fundamental classes of low mass systems.

8. Summary and Conclusions

In summary, we have presented the results of high spatial resolution HI synthesis observations of five BCDs. Our results and conclusions are summarized below.

- (1) The HI distributions extend well beyond the optical system, with a typical $D_{\text{HI}}/D_{\text{opt}}$ of 3–4. However, based on the velocity information, some of the extended gas is not in dynamical equilibrium. In fact, whereas velocity gradients were detected in all five objects, none are smoothly rotating systems.
- (2) The HI distributions are centrally peaked, in contrast to those of dIs (e.g., van Zee *et al.* 1997b). In all cases the central column density exceeds the Toomre (1964) instability criterion.
- (3) Detailed analysis of the HI distributions indicates that the neutral gas is clumpy on

spatial scales of hundreds of parsec. As seen previously in other dwarf galaxy systems, the peak gas column densities are associated with sites of active star formation. Furthermore, moderate local depressions in the neutral gas column density are associated with the most intense knots of star formation; in these regions, the column density drops 20–50%, presumably due to feedback from the star forming region.

(4) The observed neutral gas velocity dispersions, $\sim 11 \text{ km s}^{-1}$, are not unusual for star forming dwarf galaxies. With typical rotation velocities of $20\text{--}40 \text{ km s}^{-1}$, these systems are *rotation dominated*.

These observations have shed new light on the evolutionary connections between BCDs, dIs, and dEs. In particular, BCDs appear to have intrinsically different neutral gas distributions than the more quiescent dIs, perhaps explaining their higher rates of star formation. Furthermore, if BCDs are rotationally supported, as was found here for all five systems, BCDs cannot evolve into dEs without substantial loss of angular momentum. Thus, the neutral gas kinematics and distribution place strong constraints on the feasibility of many of the popular BCD evolutionary scenarios.

We thank Chris Taylor, Elias Brinks and Lisa Young for comments on a preliminary version of this paper. We also thank our anonymous referee for suggestions which improved the presentation of the paper. We thank Chris Taylor for providing us with data from previous BCD studies. We acknowledge the financial support by NSF grant AST95–53020 to JJS. Partial support from a NASA LTSARP grant No. NAGW–3189 (EDS) is gratefully acknowledged. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

Fig. 1.— Selected channels from the tapered data cube of II Zw 40. Every other channel is shown. The beam size, illustrated in the lower right panel, is 17.0×15.4 arcsec. The contours represent -3σ , 3σ , 6σ , and 12σ . The cross indicates the location of the nominal kinematic center.

Fig. 2.— Selected channels from the natural weight data cube of UGC 4483. The beam size, illustrated in the lower right panel, is 10.8×8.9 arcsec. The contours represent -3σ , 3σ , 6σ , and 12σ . The cross indicates the location of the nominal kinematic center.

Fig. 3.— Selected channels from the natural weight data cube of UM 439. The beam size, illustrated in the lower right panel, is 11.0×9.6 arcsec. The contours represent -3σ , 3σ , and 6σ . The cross indicates the location of the nominal kinematic center.

Fig. 4.— Selected channels from the natural weight data cube of UM 461. The beam size, illustrated in the lower right panel, is 10.1×8.4 arcsec. The contours represent -3σ , 3σ , and 6σ . The cross indicates the location of the nominal kinematic center.

Fig. 5.— Selected channels from the natural weight data cube of UM 462. The beam size, illustrated in the lower right panel, is 10.1×8.4 arcsec. The contours represent -3σ , 3σ , 6σ , and 12σ . The cross indicates the location of the nominal kinematic center.

II ZW 40

Fig. 6.— Moment maps of II Zw 40. (a) The HI contours from the tapered data cube are shown overlayed on an R band image. The HI contours are $1.6, 3.2, 6.4, 12.8,$ and 25.6×10^{20} atoms cm^{-2} with a beam size of 17.0×15.4 arcsec. The pixel scale of the optical image is 0.688 arcsec pixel^{-1} . (b) The integrated intensity map from the natural weight data cube. The HI contours are $2, 4, 8, 16,$ and 32×10^{20} atoms cm^{-2} . The beam size is 8.6×7.6 arcsec. (c) The HI contours from the intermediate weight data cube overlayed on an $\text{H}\alpha$ image. The HI contours are $1, 2,$ and 4×10^{21} atoms cm^{-2} with a beam size of 5.7×4.8 . The $\text{H}\alpha$ image is displayed on a logarithmic scale; the pixel scale is 0.43 arcsec pixel^{-1} . (d) The velocity field from the natural weight data cube. The contours are marked every 20 km s^{-1} .

UGC 4483

Fig. 7.— Moment maps of UGC 4483. (a) The HI contours from the tapered data cube are shown overlaid on an R band image. The HI contours are $4, 8, 16, 32, 64, 128,$ and 256×10^{19} atoms cm^{-2} with a beam size of 19.3×16.1 arcsec. The pixel scale of the optical image is 0.688 arcsec pixel^{-1} . (b) The integrated intensity map from the natural weight data cube. The HI contours are $2, 4, 8, 16,$ and 32×10^{20} atoms cm^{-2} . The beam size is 10.8×8.9 arcsec. (c) The HI contours from the intermediate weight data cube overlaid on an H α image. The HI contours are $1, 2,$ and 4×10^{21} atoms cm^{-2} with a beam size of 7.3×5.3 . The pixel scale of the H α image is 0.30 arcsec pixel^{-1} . (d) The velocity field from the natural weight data cube. The contours are marked every 5 km s^{-1} .

UM 439

Fig. 8.— Moment maps of UM 439. (a) The HI contours from the tapered data cube are shown overlayed on an B band image. The HI contours are 4, 8, 16, 32, 64, 128, and 256×10^{19} atoms cm^{-2} with a beam size of 23.3×16.3 arcsec. The pixel scale of the optical image is 0.43 arcsec pixel^{-1} . (b) The integrated intensity map from the natural weight data cube. The HI contours are 2, 4, 8, 16, and 32×10^{20} atoms cm^{-2} . The beam size is 11.0×9.6 arcsec. (c) The HI contours from the intermediate weight data cube overlayed on an $\text{H}\alpha$ image. The HI contours are 1, 2, and 4×10^{21} atoms cm^{-2} with a beam size of 7.2×5.8 . The pixel scale of the $\text{H}\alpha$ image is 0.43 arcsec pixel^{-1} . (d) The velocity field of the natural weight data cube. The contours are marked every 10 km s^{-1} .

UM 461

Fig. 9.— Moment maps of UM 461. (a) The HI contours from the smoothed natural weight data cube are shown overlayed on an B band image. The HI contours are 4, 8, 16, 32, 64, 128, and 256×10^{19} atoms cm^{-2} with a beam size of 19.6×15.5 arcsec. The pixel scale of the optical image is $0.43 \text{ arcsec pixel}^{-1}$. (b) The integrated intensity map from the natural weight data cube. The HI contours are 2, 4, 8, 16, and 32×10^{20} atoms cm^{-2} . The beam size is 10.1×8.4 arcsec. (c) The HI contours from the intermediate weight data cube overlayed on an $\text{H}\alpha$ image. The HI contours are 1, 2, and 4×10^{21} atoms cm^{-2} with a beam size of 6.6×5.2 . The pixel scale of the $\text{H}\alpha$ image is $0.43 \text{ arcsec pixel}^{-1}$. (d) The velocity field of the natural weight data cube. The contours are marked every 10 km s^{-1} .

UM 462

Fig. 10.— Moment maps of UM 462. (a) The HI contours from the tapered data cube are shown overlayed on an B band image. The HI contours are 4, 8, 16, 32, 64, 128, and 256×10^{19} atoms cm^{-2} with a beam size of 19.6×15.5 arcsec. The pixel scale of the optical image is 0.43 arcsec pixel^{-1} . (b) The integrated intensity map from the natural weight data cube. The HI contours are 2, 4, 8, 16, and 32×10^{20} atoms cm^{-2} . The beam size is 10.1×8.4 arcsec. (c) The HI contours from the intermediate weight data cube overlayed on an $\text{H}\alpha$ image. The HI contours are 1, 2, and 4×10^{21} atoms cm^{-2} with a beam size of 6.6×5.2 . The pixel scale of the $\text{H}\alpha$ image is 0.43 arcsec pixel^{-1} . (d) The velocity field of the natural weight data cube. The contours are marked every 10 km s^{-1} .

Fig. 11.— Radial HI surface densities for BCDs and dIs. The BCDs from this paper are denoted by the solid lines: 1– II Zw 40; 2– UGC 4483; 3– UM 439; 4– UM 461; 5– UM 462. The BCDs from the sample of Taylor *et al.* (1994) are denoted by dotted lines. The dIs from the sample of van Zee *et al.* (1997b) are denoted by long dashed lines.

Fig. 12.— Position–Velocity diagrams from the natural weight data cubes. The contours represent -3σ , 3σ , 6σ , 12σ , and 24σ . For all except UM 461, the rotation curves derived from tilted-ring models are superposed.

Fig. 13.— Moment map of the UM 461/2 system from the tapered data cube. The HI contours are 2, 4, 8, 16, 32, 64, 128, and 256×10^{19} atoms cm^{-2} . The beam size of the HI data is 19.6×15.5 arcsec.

Fig. 14.— HI and H α intensity profiles. Each cut is centered on the peak H α emission feature with the position angle set such that the slice will intersect additional HII regions. In each panel, the HI column density is denoted by a solid line; the H α flux (in units of counts, not on a common scale) is denoted by a dashed line. The H α resolution is approximately $2''$ while the HI maps have resolutions of approximately $5''$. The data for I Zw 18 were taken from van Zee *et al.* (1998).

Fig. 15.— (a) Peak column density as a function of metallicity. The BCD points (black squares) include I Zw 18 (van Zee *et al.* 1998) and the five BCDs in the present sample. The dIs (open squares) are from the samples of Skillman *et al.* (1988), Shostak & Skillman (1989), Lo *et al.* (1993), and van Zee *et al.* (1997b). The peak column densities have not been corrected for inclination or for beam smearing effects. (b) A histogram of peak column densities for BCDs (hatched) and dIs (open). The BCD sample includes the present sample, galaxies in Taylor *et al.* (1994), and van Zee *et al.* (1998); the dI sample also includes galaxies in Skillman *et al.* (1987), Côté (1995), Kobulnicky & Skillman (1995), and Hunter *et al.* (1996), as well as the references mentioned above. The column densities have not been corrected for inclination or beam effects, but it is suggestive that the BCDs have systematically higher column densities than dIs.

Table 1. Global Parameters
